GLOSSARY

ACRONYMS

AAD	assigned altitude deviation
ACAS	airborne collision avoidance system
ACC	area control centre
ADS-B	automatic dependent surveillance–broadcast
ASE	altimetry system error
ATC	air traffic control
ATS	air traffic services
CFL	cleared flight level
CMA	central monitoring agency
CRM	collision risk model
FAA	Federal Aviation Administration
FL	flight level
FTE	flight technical error
GMS	GPS-based monitoring system
GMU	GPS-based monitoring unit
GPS	global positioning system
GSPS	global system performance specification
HMU	height-monitoring unit
JAA	Joint Aviation Authority
LHD	large height deviation
MASPS	minimum aircraft system performance specification
MNPS	minimum navigation performance specification
NAT	North Atlantic
NAT SPG	North Atlantic Systems Planning Group
NOTAM	notice to airmen
PDF	probability density function
RGCSP	Review of the General Concept of Separation Panel
RMA	regional monitoring agency
RNAV	area navigation
RPG	regional planning group
RVSM	reduced vertical separation minimum
SMS	safety management system
SSE	static source error
SSR	secondary surveillance radar
TLS	target level of safety
TVE	total vertical error
VSM	vertical separation minimum

DEFINITIONS

The following definitions are intended to clarify certain specialized terms used in this manual.

Aberrant aircraft. Those aircraft which exhibit measured height-keeping performance that is significantly different from the core height-keeping performance measured for the whole population of aircraft operating in RVSM airspace.

Aircraft type groupings. Aircraft are considered to belong to the same group if they are designed and assembled by one manufacturer and are of nominally identical design and build with respect to all details which could influence the accuracy of height-keeping performance.

Airworthiness approval. The process of assuring the State authority that aircraft meet an RVSM MASPS. Typically, this would involve an operator meeting the requirements of the aircraft manufacturer service bulletin for that aircraft and having the State authority verify the successful completion of that work.

Altimetry system error (ASE). The difference between the altitude indicated by the altimeter display, assuming a correct altimeter barometric setting, and the pressure altitude corresponding to the undisturbed ambient pressure.

Altimetry system error stability. Altimetry system error for an individual aircraft is considered to be stable if the statistical distribution of altimetry system error is within agreed limits over an agreed period of time.

Altitude-keeping device. Any equipment which is designed to automatically control the aircraft to a referenced pressure altitude.

Assigned altitude deviation (AAD). The difference between the transponder Mode C altitude and the assigned altitude/flight level.

Automatic altitude-keeping device. Any equipment which is designed to automatically control the aircraft to a referenced pressure-altitude.

Collision risk. The expected number of mid-air aircraft accidents in a prescribed volume of airspace for a specific number of flight hours due to loss of planned separation.

Note.— One collision is considered to produce two accidents.

Flight technical error (FTE). The difference between the altitude indicated by the altimeter display being used to control the aircraft and the assigned altitude/flight level.

Height-keeping capability. The aircraft height-keeping performance that can be expected under nominal environmental operating conditions with proper aircraft operating practices and maintenance.

Height-keeping performance. The observed performance of an aircraft with respect to adherence to cleared flight level.

Non-compliant aircraft. An aircraft configured to comply with the requirements of an RVSM MASPS which, through height monitoring, is found to have a total vertical error (TVE) or an assigned altitude deviation (AAD) of 90 m (300 ft) or greater or an altimetry system error (ASE) of 75 m (245 ft) or more.

NOTAM. A notice distributed by means of telecommunication containing information concerning the establishment, condition or change in any aeronautical facility, service, procedure or hazard, the timely knowledge of which is essential to personnel concerned with flight operations.

Occupancy. A parameter of the collision risk model which is twice the count of aircraft proximate pairs in a single dimension divided by the total number of aircraft flying the candidate paths in the same time interval.

Operational error. Any vertical deviation of an aircraft from the correct flight level as a result of incorrect action by air traffic control (ATC) or the aircraft crew.

Overall risk. The risk of collision due to all causes, which includes the technical risk (see definition) and all risk due to operational errors and in-flight contingencies.

Passing frequency. The frequency of events in which two aircraft are in longitudinal overlap when travelling in the opposite or same direction on the same route at adjacent flight levels and at the planned vertical separation.

RVSM approval. The term used to describe the successful completion of airworthiness approval and operational approval (if required).

Target level of safety (TLS). A generic term representing the level of risk which is considered acceptable in particular circumstances.

Technical risk. The risk of collision associated with aircraft height-keeping performance.

Total vertical error (TVE). The vertical geometric difference between the actual pressure altitude flown by an aircraft and its assigned pressure altitude (flight level).

Track. The projection on the earth's surface of the path of an aircraft, the direction of which path at any point is usually expressed in degrees from North (true, magnetic or grid).

Vertical separation. The spacing provided between aircraft in the vertical plane to avoid collision.

Vertical separation minimum (VSM). VSM is documented in the *Procedures for Air Navigation Services — Air Traffic Management* (PANS-ATM, Doc 4444) as being a nominal 300 m (1 000 ft) below FL 290 and 600 m (2 000 ft) above FL 290 except where, on the basis of regional agreement, a value of less than 600 m (2 000 ft) but not less than 300 m (1 000 ft) is prescribed for use by aircraft operating above FL 290 within designated portions of the airspace.

Chapter 1

INTRODUCTION

1.1 BACKGROUND

1.1.1 In the late 1950s it was recognized that, as a result of the reduction in pressure-sensing accuracy of barometric altimeters with increasing altitude, there was a need above a certain flight level (FL) to increase the prescribed vertical separation minimum (VSM) of 300 m (1 000 ft). In 1960, an increased VSM of 600 m (2 000 ft) was established for use between aircraft operating above FL 290 except where, on the basis of regional air navigation agreement, a lower flight level was prescribed for the increase. The selection of FL 290 as the vertical limit for the 300 m (1 000 ft) VSM was not so much an empirically-based decision but rather a function of the operational ceiling of the aircraft at that time. In 1966, this changeover level was established at FL 290 on a global basis. At the same time, it was considered that the application of a reduced VSM above FL 290, on a regional basis and in carefully prescribed circumstances, was a distinct possibility in the not too distant future. Accordingly, ICAO provisions stated that such a reduced VSM could be applied under specified conditions within designated portions of airspace on the basis of regional air navigation agreement.

1.1.2 It has long been recognized that any decision concerning the feasibility of reducing the VSM above FL 290 could not be based upon operational judgement alone, but would need to be supported by a rigorous assessment of the risk associated with such a reduction of separation. The lack of a clear-cut method of achieving such an assessment was the primary cause of the failure of various attempts to determine the feasibility of a reduced VSM.

1.1.3 In the mid-1970s, the series of world fuel shortages and the resultant rapid escalation of fuel costs, allied to the growing demand for a more efficient use of the available airspace, emphasized the need for a detailed appraisal of the proposal to reduce the VSM above FL 290. Thus, at its fourth meeting (in 1980), the ICAO Review of the General Concept of Separation Panel (RGCSP) concluded that, despite the cost and time involved, the potential benefits of reducing the VSM above FL 290 to 300 m (1 000 ft) were so great that States should be encouraged to conduct the necessary major evaluations.

1.1.4 In 1982, coordinated by the RGCSP, States initiated programmes to study comprehensively the question of reducing the VSM above FL 290. Studies were carried out by Canada, Japan, Member States of EUROCONTROL (France, Federal Republic of Germany, Kingdom of the Netherlands and United Kingdom), Union of Soviet Socialist Republics and United States, and in December 1988 the results were considered by the RGCSP at its sixth meeting (RGCSP/6).

1.1.5 These studies employed quantitative methods of risk assessment to support operational decisions concerning the feasibility of reducing the VSM. The risk assessment consisted of two elements: first, risk estimation, which concerns the development and use of methods and techniques with which the actual level of risk of an activity can be estimated; and second, risk evaluation, which concerns the level of risk considered to be the maximum tolerable value for a safe system. The level of risk that is deemed acceptable was termed the target level of safety (TLS).

1.1.6 The process for estimating risk in the vertical plane using the collision risk model (CRM) assumed that collisions result solely from vertical navigation errors of aircraft to which procedural separation had been correctly applied. The TLS was derived to apply to this source of collision risk alone; it does not address risk from other sources, such as height deviations due to turbulence, responses to airborne collision avoidance system alerts, emergency descents and operational errors in the issuance of, or compliance with, air traffic control (ATC) instructions.

1.1.7 The recognition of several sources of risk in addition to vertical navigation errors played a role in the choice of TLS values made by various States during their studies. Several approaches were followed in order to establish an appropriate range of values, including all en-route mid-air collisions and the implicit period between collisions, and adjusting the TLS until the period of time became acceptable. Nevertheless, the primary approach, and the traditional manner, was to use historical data from global sources, predicted forward to approximately the year 2000 to provide safety improvement and to apportion resultant risk budgets to derive the vertical collision risk element.

1.1.8 The derived values for the TLS ranged between 1×10^{-8} and 1×10^{-9} fatal accidents per aircraft flight hour. On the basis of these figures, it was agreed that an assessment TLS of 2.5×10^{-9} fatal accidents per aircraft flight hour would be used to assess the technical feasibility of a 300 m (1 000 ft) VSM above FL 290 and also to develop aircraft height-keeping capability requirements for operating in a 300 m (1 000 ft) VSM.

1.1.9 Using the assessment TLS of 2.5×10^{-9} fatal accidents per aircraft flight hour, RGCSP/6 concluded that a 300 m (1 000 ft) VSM above FL 290 was technically feasible. This technical feasibility refers to the fundamental capability of aircraft height-keeping systems, which could be built, maintained and operated in such a manner that the expected, or typical, performance is consistent with safe implementation and use of a 300 m (1 000 ft) VSM above FL 290. In reaching this conclusion on technical feasibility, the panel found it necessary to establish:

- a) airworthiness performance requirements embodied in a comprehensive minimum aircraft system performance specification (MASPS) for all aircraft utilizing the reduced separation;
- b) new operational procedures; and
- c) a comprehensive means of monitoring the safe operation of the system.

1.1.10 It is important to emphasize that the assessment TLS did not address all causes of risk of collision in the vertical plane. In the first edition of this guidance material, regional planning authorities were advised of the necessity to institute measures to ensure that the risks associated with operational errors and emergency actions did not increase in the 300 m (1 000 ft) VSM environment. In the North Atlantic (NAT) Region, which on 27 March 1997 became the first ICAO region to implement the reduced vertical separation minimum (RVSM), it was agreed that a more formal approach was necessary to assessing all causes of risk in the vertical plane. On the basis of the experience gained in the monitoring and analysis of the causes of operational errors in NAT minimum navigation performance specification (MNPS) airspace, the NAT Systems Planning Group (NAT SPG) agreed that limiting the risk of collision due to the loss of planned vertical separation as a consequence of such events should receive attention at least equal to that devoted to limiting the effects of technical errors (errors of aircraft height-keeping systems). Therefore, in addition to the TLS for technical errors, i.e. 2.5×10^{-9} fatal accidents per aircraft flight hour, an overall TLS of 5×10^{-9} fatal accidents per aircraft flight hour resulting from a loss of vertical separation due to any cause was adopted.

1.2 PURPOSE OF THE MANUAL

1.2.1 The basic purpose of this manual is to provide regional planning groups (RPGs) with a basis for the revision of documents, procedures and programmes to enable the maintenance of a 300 m (1 000 ft) VSM between FL 290 and FL 410 inclusive within their particular regions in accordance with the criteria and requirements developed by ICAO.

1.2.2 This manual also provides:

- a) guidance to State aviation authorities on those measures necessary to ensure that the criteria and requirements are met within their area of responsibility; and

- b) background information for operators to assist them in the development of operating manuals and flight crew procedures.

1.3 CONTENT AND PRESENTATION

1.3.1 The title of this manual and the sequence of material in this third edition reflect amended content and presentation that focus on continuing RVSM operations, in contrast to the first and second editions that focused on implementation. These changes have been made on the basis that RVSM has been successfully implemented globally. Chapter 2 describes the general RVSM requirements in terms of inter alia, safety, required aircraft height-keeping performance, and operating aspects. Chapter 3 describes specific aircraft RVSM requirements and approval aspects, Chapter 4 gives general guidance on procedures, for both ATC and flight crew, and Chapter 5 provides information on system monitoring, including the responsibilities and tasks of authorities in RVSM performance monitoring. Appendix A contains guidance on the quantitative aspects of system performance monitoring, and Appendix B provides a list of reference documentation, such as regional documentation developed in the context of regional RVSM implementation programmes.

1.3.2 In this manual, RVSM refers to a vertical separation minimum of 300 m (1 000 ft) between FL 290 and FL 410 inclusive.

Chapter 2

GENERAL REQUIREMENTS

2.1 SAFETY OBJECTIVES

2.1.1 Continuity of RVSM operations can be based on safety assessments undertaken at least annually, demonstrating that RVSM safety objectives are being maintained. Where practicable, assessments may be undertaken on a more frequent basis to ensure any change to system risk is identified and controlled as early as possible. The safety assessment may include using a CRM for the airspace in accordance with the guidance provided in this manual (more detailed information on CRM methodologies is contained in the documents referenced in Appendix B). Alternatively, safety assessments may be part of a continuing monitoring process based on a safety management system (SMS) approach to monitoring safety. This ongoing process seeks to capture data on a continuing basis and is aimed at identifying system risk at its earliest stages. This SMS process aims to capture safety performance indicators in order to measure their levels of safety when compared to safety performance targets. These safety performance targets are set in agreement with oversight authorities in order to meet higher-level acceptable levels of safety.

2.1.2 Safety objectives for RVSM implementation have been set for both technical risk and overall risk and are as follows.

Safety objective for technical risk

2.1.3 Technical risk is the risk of collision associated with aircraft height-keeping performance. Risk associated with operational errors (e.g. controller/pilot errors) and in-flight contingencies is not included.

2.1.4 The RVSM safety objective for technical risk is a TLS of 2.5×10^{-9} fatal accidents per aircraft flight hour. This value for technical risk was used to derive the global system performance specification and the global height-keeping performance specification, which are detailed in 2.2 and 2.3, respectively.

Safety objective for overall risk

2.1.5 Overall risk is the risk of collision due to all causes, which includes the technical risk (see above) and all risk due to operational errors and in-flight contingencies, such as but not limited to pilot/controller errors, height deviations due to emergency procedures, and turbulence.

2.1.6 The RVSM safety objective for overall risk should be set by regional agreement. Due account should be taken of existing ICAO guidance on safety objectives and of safety objectives applied in other regions. To this end, attention is drawn to:

- a) the guidance provided in the *Performance-based Navigation (PBN) Manual* (Doc 9613) which, with regard to spacing between parallel tracks or between parallel RNAV route centre lines based on RNP type, recommends that for implementation of en-route systems after the year 2000, a TLS of 5×10^{-9} fatal accidents per flying hour per dimension should be applied;
- b) SMS-based metrics and methods of qualitative assessment providing an acceptable level of safety performance may be established by States and, as appropriate, implemented by regional agreement;

- c) the overall safety objective applied for RVSM implementation globally, i.e. a TLS of 5×10^{-9} fatal accidents per aircraft flight hour resulting from a loss of vertical separation due to any cause (see 1.1.10); and
- d) the reference list in Appendix B to this manual.

2.1.7 Guidance on the methodologies to estimate risk associated with RVSM is contained in Chapter 5, system performance monitoring.

2.1.8 Regional authorities should take into account all possible means of quantifying and reducing the level of risk of collision resulting from operational errors and in-flight contingencies in RVSM airspace. Whilst the frequency of occurrence of these events is not considered to be a function of the separation minimum applied, it will be essential for RPGs to institute measures to ensure that the risk due to operational errors and in-flight contingencies does not increase. Guidance on the type of measures to be taken by RPGs, ATC and flight crews is outlined in Chapters 5 and 6.

2.1.9 The results of safety assessments compared against the accepted TLS will provide RPGs with an indication of the current risk within the airspace in which an assessment was undertaken. In the event this risk exceeds the accepted TLS, the RPG should initiate remedial actions in order to attempt to reduce the level of risk to at least the TLS. For it to do so, an RPG will need to have a clear understanding of the reasons driving the risk increase. Therefore it is important that any safety assessments undertaken are of such detail that underlying causes of risk in the airspace are identified. As a result, a qualitative analysis of operational errors and large height deviations is an important activity to be included in the safety assessment process.

2.2 GLOBAL SYSTEM PERFORMANCE SPECIFICATION

2.2.1 The global system performance specification is a statement of the parameters that form the basis for defining the integrated set of requirements for aircraft height-keeping, aircraft systems, aircraft operating procedures, ATC procedures and monitoring practices presented in this manual. The global system performance specification defines the height-keeping performance necessary to meet the safety goal for RVSM technical risk (see 2.1). This level of height-keeping performance depends on specific values of important airspace parameters affecting the risk of collision should vertical separation be lost. The height-keeping performance requirement of the system performance specification is expressed as the maximum value for the probability that aircraft will lose vertical separation equal to the RVSM value, $P_z(1\ 000)$. The important airspace parameters concern the frequency with which aircraft pass while having procedural vertical separation equal to RVSM and actual horizontal separation less than the horizontal size of an aircraft. These important airspace parameters may be expressed in different ways, depending on the route structure of the airspace.

2.2.2 The global system performance specification was originally derived for opposite-direction traffic. In that case, the important airspace parameters are the frequency with which aircraft pass while having procedural vertical separation equal to RVSM and no nominal horizontal separation, and the standard deviation of the error with which aircraft maintain assigned track in the lateral dimension. The quantitative statements of the global system performance specification are:

- a) a passing frequency equal to 2.5 opposite-direction passings per aircraft flight hour;
- b) a standard deviation of lateral path-keeping error equal to 550 m (0.3 NM); and
- c) a probability that two aircraft will lose procedural vertical separation of RVSM value, $P_z(1\ 000)$, equal to 1.7×10^{-8} .

The values for passing frequency and the standard deviation of lateral path-keeping were chosen to forecast future global airspace conditions. These choices reflect the intention to ensure that the TLS will continue to be met with the anticipated increase in global traffic volume and expected technological improvements in navigation.

2.2.3 The global system performance specification in 2.2.2 is based on factoring the frequency with which aircraft pass, with an actual horizontal separation of less than the horizontal size of an aircraft, into a longitudinal and a lateral component. A standard deviation of lateral path-keeping error of 550 m (0.3 NM) produces a probability of lateral overlap of 0.058 for aircraft on the same track. The combined effect of the requirements of 2.2.2 a) and b) on vertical collision risk is equal to $2.5 \times 0.058 = 0.145$. Therefore, an equivalent but more generally applicable quantitative statement of the global system performance specification is:

- a) a frequency of opposite-direction passing events involving lateral overlap equal to 0.145 passings per aircraft flight hour; and
- b) a probability that two aircraft will lose procedural vertical separation of RVSM value, $P_z(1\ 000)$, equal to 1.7×10^{-8} .

2.2.4 Although the global system performance specification was derived and formulated in terms of opposite-direction traffic, it also applies to other route structures, e.g. same-direction traffic, crossing traffic and combinations thereof. For each type of route structure, an equivalent form of the global system performance specification exists (for further details see Chapter 5, 5.2.5 and Appendix A).

Trade-off between global system performance specification parameters

2.2.5 The parameters of the global system performance specification consist of the height-keeping performance on the one hand and the specified airspace parameters on the other. This allows for two types of trade-offs between these parameters, depending on the value of the probability of vertical overlap, $P_z(1\ 000)$, i.e. whether $P_z(1\ 000)$ is equal to or well below the value of 1.7×10^{-8} , as defined in the global system performance specification. However, $P_z(1\ 000)$ may never be allowed to exceed the value of 1.7×10^{-8} .

2.2.6 The first type of trade-off that may be used is between the airspace parameters of passing frequency and the standard deviation of lateral path-keeping error, provided that the probability of vertical overlap is not greater than 1.7×10^{-8} . These two airspace parameters may be traded off against one another provided that their joint effect on vertical collision risk is not greater than that due to an opposite-direction passing frequency of 2.5 passings per aircraft flight hour and a lateral path-keeping error standard deviation of 550 m (0.3 NM). The numerical bound for this joint effect is 0.145 (see also 2.2.3). Thus, either a higher passing frequency in combination with less accurate lateral path-keeping or a lower passing frequency in combination with more accurate lateral path-keeping would be allowed as long as the bound of 0.145 was not exceeded. Note that this trade-off for opposite-direction traffic is implicit in the more general form of the global system performance specification in 2.2.3.

2.2.7 The second type of trade-off is between the probability of vertical overlap, $P_z(1\ 000)$, and the airspace parameters, provided that the probability of vertical overlap is well below the value of 1.7×10^{-8} . The margin provided by $P_z(1\ 000)$ may then be used to increase the upper bound of 0.145 for the combined effect of passing frequency and lateral path-keeping error standard deviation. Within this larger upper bound, the two airspace parameters may be varied as set out in 2.2.6. This second type of trade-off should be performed with great care since the height-keeping performance of the aircraft population may change over time, e.g. aircraft new to the airspace under consideration are only required to meet the global $P_z(1\ 000)$ value of 1.7×10^{-8} and not a lower value.

2.2.8 It should be noted that conducting the trade-off process is more complex than carrying out a straightforward check against a fixed upper bound. The benefit, however, is more flexibility with regard to the allowable parameter values.

2.3 GLOBAL HEIGHT-KEEPING PERFORMANCE SPECIFICATION

2.3.1 In order to ensure safe transition between regions, a global height-keeping performance specification was developed so that, if met, the required $P_z(1\ 000)$ value of the global system performance specification would also be met. The global height-keeping performance specification applies to the aggregate of height-keeping errors of individual aircraft and simultaneously satisfies the following four requirements:

- a) proportion of height-keeping errors beyond 90 m (300 ft) in magnitude is less than 2.0×10^{-3} ;
- b) proportion of height-keeping errors beyond 150 m (500 ft) in magnitude is less than 3.5×10^{-6} ;
- c) proportion of height-keeping errors beyond 200 m (650 ft) in magnitude is less than 1.6×10^{-7} ; and
- d) proportion of height-keeping errors between 290 m and 320 m (950 ft and 1 050 ft) in magnitude is less than 1.7×10^{-8} .

2.3.2 The above requirements have been the basis for the development of the RVSM minimum aircraft system performance specification (MASPS) (see Chapter 3, 3.1). The global height-keeping performance specification is also applied in the process to monitor $P_z(1\ 000)$ (see Chapter 5, 5.2).

Chapter 3

AIRCRAFT REQUIREMENTS AND APPROVAL

3.1 RVSM HEIGHT-KEEPING PERFORMANCE

3.1.1 Altimetry system and altitude-keeping characteristics were developed to satisfy the global height-keeping performance specification as described in 2.3. They describe the performance level that aircraft need to be capable of achieving in service, exclusive of Human Factors and extreme environmental influences, if the airspace system TVE requirements are to be satisfied.

3.1.2 The aforementioned characteristics were translated by technical bodies into airworthiness standards through the assessment of the characteristics of ASE and automatic altitude control. These standards comprise the in-service aircraft height-keeping requirements for RVSM operations and form part of the RVSM MASPS. The RVSM MASPS includes specifications and procedures for the separate aspects of type approval, release from production, and continued airworthiness and is included in the following documents for global application:

- a) Joint Aviation Authority (JAA) Temporary Guidance Leaflet (TGL) No. 6 — *Guidance Material on the Approval of Aircraft and Operators for Flight in Airspace above Flight Level 290 where a 300 m (1 000 ft) Vertical Separation Minimum is Applied* — or any subsequent version thereof; or
- b) Federal Aviation Administration (FAA) Document 91-RVSM, *Guidance Material on the Approval of Operators/Aircraft for RVSM Operations*.

These documents are an acceptable means for RVSM approval and were developed in compliance with the guidance material in this manual.

3.2 AIRWORTHINESS APPROVAL

Introduction

3.2.1 Airworthiness approval must in all cases be in accordance with the requirements of the RVSM MASPS. As stated in 3.1.2, the RVSM MASPS, in addition to characterizing the ASE and automatic height-keeping capability requirements, also contains specifications and procedures for type approval and continued airworthiness.

3.2.2 All approvals will be applicable to an individual aircraft or to a group of aircraft, as defined in 3.2.3, that are nominally identical in aerodynamic design and items of equipment contributing to height-keeping accuracy.

Definition of aircraft type groupings

3.2.3 For aircraft to be considered as part of a group for the purposes of airworthiness approval, the following conditions should be satisfied:

- a) the aircraft should have been constructed to a nominally identical design and should be approved on the same Type Certificate (TC), TC amendment, or Supplemental TC, as applicable;

Note.— For derivative aircraft, it may be possible to use the data from the parent configuration to minimize the amount of additional data required to show compliance. The extent of additional data required will depend on the nature of the differences between the parent aircraft and the derivative aircraft.

- b) the static system of each aircraft should be nominally identical. The static source error (SSE) corrections should be the same for all aircraft of the group; and
- c) the avionics units installed on each aircraft to meet the minimum RVSM equipment criteria should comply with the manufacturer's same specification and have the same part number.

Note.— Aircraft that have avionics units which are of a different manufacturer or part number may be considered part of the group if it can be demonstrated that this standard of avionics equipment provides equivalent system performance.

3.2.4 If an airframe does not meet the conditions of 3.2.3 a) to c) to qualify as a part of a group, and is presented as an individual airframe for approval, it will be considered to be a non-group aircraft. The significance of this is that the certification processes for group and non-group aircraft are different.

Continued airworthiness

3.2.5 It is imperative that all aircraft continue, during their service life, to satisfy the requirements of the RVSM MASPS. While height-monitoring data from independent sources, as recommended by ICAO, should help to detect any long-term deterioration in altimetry system performance, it is nevertheless essential that certifying authorities ensure that, as part of the approval process, operator maintenance and inspection practices are reviewed and updated to reflect the specific airworthiness requirements applicable to RVSM operations.

3.3 STATE RVSM APPROVAL

Approval process

3.3.1 Where RVSM is applied, the specific aircraft type or types that the operator intends to use will need to be approved by the State of Registry of the aircraft or of the aircraft operator. RVSM approval will encompass the following elements:

- a) *Airworthiness approval (including continued airworthiness).* The aircraft will be approved as meeting the requirements of the appropriate State airworthiness document derived from the height-keeping capability requirements as defined by the RVSM MASPS. Furthermore, the aircraft altimetry and height-keeping equipment must be maintained in accordance with approved procedures and servicing schedules; and
- b) *Operational approval.* As defined by ICAO regional air navigation agreements, it may be necessary for an operator to hold a separate RVSM-specific operational approval in addition to an RVSM airworthiness approval to operate in RVSM airspace. Section 4.2 contains guidance on operational procedures that an operator may need to adopt for such airspace where RVSM is applied, including advice on the material that may need to be submitted for review by the authority responsible.

Validity of approval

3.3.2 RVSM approval issued for one region will always be valid for RVSM operations in another region provided specific restrictions have not been imposed on the operator by the State of the Operator or State of Registry.

Confirmation of approval status

3.3.3 Continuity of RVSM operations is dependent on the establishment of an aircraft approval confirmation process, which is intended to exclude unqualified aircraft and operators from operating in RVSM airspace unless the appropriate separation is applied. The process may have regional variations, but the primary responsibility for confirmation of the approval status of an aircraft/operator must rest with the State of the Operator/State of Registry. The confirmation process will be facilitated by the application of the following measures:

- a) maintaining a comprehensive record of all approvals granted for operations in RVSM airspace;
- b) providing the approvals records in 3.3.3 a) to the regional monitoring agency (RMA) for inclusion in its regional RVSM-approvals database; and
- c) including a check of the approval status of aircraft/operators in the schedule of routine in-flight inspections.

3.3.4 At the appropriate level, a secondary responsibility should rest with the air traffic services (ATS) provider States to institute routine checks of the approval status of aircraft operating within their area of authority and intending to operate in RVSM airspace. Apart from the scrutiny activities conducted by the relevant RMA, this responsibility could be met by:

- a) scrutinizing ATS flight plans;
- b) conducting cross-checks against the regional RVSM-approvals database, taking into account the currency of its contents; and
- c) querying operators that are suspected of not being in compliance with the airspace requirements.

3.3.5 Depending on State regulations, ATC clearances may be withheld for operations that are not in compliance with the airspace requirements.

3.3.6 In conjunction with the ATS provider, a further level of confirmation of approval can be affected by the RMA of a region in which RVSM applies. This can be achieved by the RMA taking action, following a query by a controlling authority, to obtain confirmation of approval status from the State of the Operator/State of Registry of aircraft which are not listed in an RVSM-approvals database.

Note.— The role of the RMA is covered in detail in 5.4.4.

3.3.7 The State of the Operator/State of Registry should formulate policies and courses of action with respect to aircraft/operators that are found to be operating in RVSM airspace without approval, which could jeopardize the safety of other users of the airspace.

Chapter 4

PROCEDURES

4.1 GENERAL PROCEDURES

Cruising levels

4.1.1 The table of cruising levels specified in Appendix 3 of Annex 2 to the Convention on International Civil Aviation, for use in RVSM airspace, shall be used.

4.2 FLIGHT CREW OPERATING PROCEDURES

In-flight procedures

4.2.1 Generally, flight crew operating procedures in RVSM airspace are no different from those in any other airspace; however, the continuity of RVSM operations will require periodic review of procedures specific to a region, e.g. contingency procedures, and should be reflected in regional documentation. Given the safety requirements and the effect large height deviations could have on the risk levels, crews should be reminded to exercise vigilance to minimize the occurrence of deviations from the cleared flight level. To this end, during routine training, flight crews should be reminded of the importance of adhering to the following in-flight procedures:

- a) in level cruise it is essential that the aircraft be flown at the cleared flight level (CFL). This requires that particular care be taken to ensure that ATC clearances are fully understood and complied with. Except in the event of an emergency, the aircraft should not intentionally depart from CFL without a clearance from ATC;
- b) during cleared transition between levels, the aircraft should not be allowed to overshoot or undershoot the new flight level by more than 45 m (150 ft);

Note.—The transition should be accomplished using the altitude capture feature of the automatic altitude-keeping device, if installed.

- c) an automatic altitude-keeping device should be operative and engaged during level cruise, except when circumstances such as turbulence or the need to re-trim the aircraft require its disengagement. In any event, adherence to cruise altitude should be done by reference to one of the two altimeters required by the RVSM MASPS;
- d) the altitude-alerting device should be operating and engaged;
- e) regular (hourly) cross-checks between the altimeters should be made, and a minimum of two RVSM MASPS-compliant systems must agree within 60 m (200 ft). Failure to meet this condition will require that the system be reported as defective and notified to ATC;

- f) the operating altitude-reporting transponder should be connected to the RVSM MASPS-compliant altimetry system being used to control the aircraft;
- g) before entering RVSM airspace, the pilot should review the status of equipment required. The following equipment should be operating normally:
 - 1) two altitude measurement systems, as defined by the RVSM MASPS;
 - 2) automatic altitude-keeping device(s);

Note.— Redundancy requirements for altitude-keeping devices should be established by regional agreement after an evaluation of such criteria as mean time between failures, length of flight segments and availability of direct pilot controller communications and radar surveillance.

- 3) at least one altitude-reporting transponder (if required for operation in that specific RVSM airspace) capable of being switched to operate from either of the two altimetry systems required by the RVSM MASPS; and
- 4) one altitude-alerting device;

Should any of this equipment fail prior to the aircraft entering RVSM airspace, the pilot should request a new clearance so as to avoid flight in this airspace;

- h) the following contingency procedures should be adhered to after entering RVSM airspace:
 - 1) the pilot should notify ATC of contingencies (equipment failures, weather conditions) in which the ability to maintain CFL is affected and coordinate a plan of action (see 4.3.2);
 - 2) equipment failures should be notified to ATC. Some examples are:
 - i) failure of all automatic altitude-keeping devices on board the aircraft;
 - ii) loss of redundancy of altimetry systems, or any part of these, on board the aircraft;
 - iii) failure of all altitude-reporting transponders;
 - iv) loss of thrust on an engine necessitating descent; and
 - v) any other equipment failure affecting the ability to maintain CFL;
 - 3) the pilot should notify ATC when encountering severe turbulence; and
 - 4) if unable to notify ATC and obtain an ATC clearance prior to deviating from the assigned CFL, the pilot should follow established contingency procedures as defined by the region of operation and obtain ATC clearance as soon as possible.

Operations manual

4.2.2 Where applicable, aircraft operators should revise their operations manuals to reflect any differences in standard operating procedures that result from operation in RVSM airspace.

4.3 ATC PROCEDURES

General

4.3.1 The continuity of RVSM operations safely in relation to the provision of air navigation services requires that ATC procedures be periodically reviewed and appropriate recurrent training provided. As a basis for the periodic review of regional procedures, consideration should be given to the appropriate action to be taken by controllers in the following situations, as applicable:

- a) aircraft known not to be suitably equipped are flight planned into RVSM airspace;
- b) an aircraft informs ATC that the capability to maintain a CFL appropriate to RVSM requirements has been lost;
- c) the pilot advises that the automatic altitude-keeping device has been turned off; and
- d) the displayed altitude differs from the CFL by 90 m (300 ft) or more.

Note 1.— While not necessary to support RVSM operations, the availability of altitude display is beneficial.

Note 2.— Surveillance systems should be capable of supporting RVSM operations.

ATC contingency procedures

4.3.2 In addition to emergency conditions that require immediate descent, such as loss of thrust or pressurization, ATC shall be made aware of any conditions that may make it impossible for an aircraft to maintain its CFL. Controllers should be trained regarding the appropriate action to take in the event that they are notified by the pilot of any such condition, as described in 4.2.1 h). Suggested actions in the event of such an occurrence are:

- a) obtain the pilot's intentions;
- b) assess the traffic situation to determine if the aircraft can be accommodated through the provision of lateral, longitudinal or increased vertical separation and, if so, apply the appropriate minimum;
- c) when the aircraft cannot be accommodated in accordance with b), ascertain if the aircraft can maintain altitude in accordance with the requirements applicable below RVSM airspace. If so, and if the pilot confirms it to be operationally feasible, the controller should issue a revised clearance to a level outside RVSM airspace when traffic permits; and
- d) handle aircraft that cannot be accommodated in accordance with either b) or c) as an emergency and take whatever action is necessary to provide the appropriate separation.

Military operations

4.3.3 States are reminded of the recognized responsibility in regard to military traffic as specified in the *Procedures for Air Navigation Services — Air Traffic Management* (PANS-ATM, Doc 4444), Chapter 16. In this regard, procedures must be developed and periodically reviewed in order to accommodate military flight operations that do not meet the equipment requirements of RVSM MASPS (see Chapter 3, 3.1 to 3.2). These procedures must specify how

military flight operations in RVSM airspace are to be accommodated, but segregated from air traffic being provided with a 300 m (1 000 ft) VSM above FL 290. Suggested methods of accomplishing this are:

- a) providing temporary airspace reservations;
- b) providing block altitudes; and
- c) providing special routes applicable only to the mass movement of military aircraft on a temporary basis.

Meteorological conditions

4.3.4 Meteorological conditions that can cause turbulence which can be detrimental to accurate height-keeping include:

- a) gravity shear waves;
- b) thunderstorms;
- c) orographic flow.

4.3.5 Orographic flow, more commonly known as mountain wave activity, has been identified as being particularly detrimental to accurate height-keeping. Prior to implementation of RVSM, States known to have airspace susceptible to orographic flow should:

- a) assign responsibility for forecasting such conditions; and
- b) detail the action required by ATC on receipt of such forecasts.

4.3.6 When reports of severe turbulence are received, ATC must ascertain the capability of the aircraft to maintain CFL. Upon confirmation that meteorological conditions are affecting, or are likely to affect, height-keeping accuracy, ATC should be required to provide alternative separation as soon as possible. Additionally, when any of the meteorological conditions listed in 4.3.4 are expected to prevail over an area for an extended time period, the appropriate ATC authority should consider:

- a) issuing a NOTAM specifying the routes or area affected; and
 - b) temporarily suspending the use of 300 m (1 000 ft) VSM in the affected area.
-

Chapter 5

SYSTEM PERFORMANCE MONITORING

5.1 REQUIREMENT FOR MONITORING

5.1.1 System performance monitoring is necessary to ensure that the continued operation of RVSM meets the safety objectives (see 2.1). For practical purposes, a distinction can be made about the monitoring process in the context of:

- a) the risk associated with the aircraft technical height-keeping performance (technical risk); and
- b) the overall risk, i.e. due to all causes.

5.1.2 For 5.1.1 a), the monitoring process should aim to achieve the following:

- a) provide confidence that the technical TLS of 2.5×10^{-9} fatal accidents per aircraft flight hour is being met;
- b) provide guidance on the efficacy of the RVSM MASPS and on the effectiveness of altimetry system modifications; and
- c) provide evidence of ASE stability.

The monitoring objective of 5.1.2 a) can be achieved by an accepted method of assessing the collision risk due to the loss of vertical separation, based on the use of the Reich CRM. Further guidance on the process and methods of achieving the monitoring objectives of 5.1.2 a), b) and c) is provided in 5.2.

5.1.3 For 5.1.1 b), the monitoring process should take into account the additional risk associated with operational errors and in-flight contingencies. This part of the monitoring process is aimed particularly at providing confidence that the regionally agreed overall safety objectives are being met. Guidance on monitoring system performance in terms of the risk due to operational errors and in-flight contingencies is provided in 5.3.

5.2 MONITORING THE TECHNICAL PERFORMANCE

Parameters of the collision risk model

5.2.1 In order to provide confidence that the technical TLS is being met (objective 5.1.2. a)), the values of particular parameters of the CRM need to be assessed through monitoring on a continual basis.

5.2.2 The CRM parameters fall into two groups from the standpoint of monitoring requirements and have been depicted in Figure 5-1. The first group consists of two parameters that are critical to safety assessment. The first parameter of this group (Item a) in Figure 5-1) is a measure of the height-keeping performance of the overall aircraft population, termed the “vertical overlap probability” and denoted as $P_z(1\ 000)$. The second (Item b) in Figure 5-1) is an

airspace parameter characterizing the exposure to vertical collision risk, i.e. a measure of the number of aircraft passing events involving horizontal overlap per aircraft per hour. For the cases of same- and opposite-direction traffic, this parameter may be factored into two parts: one part is a measure of the number of aircraft passing events (involving longitudinal overlap) per aircraft flying hour, termed the “passing frequency;” and the other part is a measure of the lateral path-keeping performance, termed the “lateral overlap probability” and denoted as $P_y(0)$.

5.2.3 The second group of CRM parameters, which includes such things as aircraft speed and length, is less demanding in terms of the resources required to collect the requisite data. This is because the CRM is relatively insensitive to these parameter values and also because these values are not expected to change substantially over the planning horizon of this manual. They should be reassessed periodically to ensure that their values reflect the current RVSM airspace system.

5.2.4 Many different combinations of the parameter values of the first group may lead to compliance with the technical TLS. One particular combination of such values is that used in the initial assessment which led to the first implementation of RVSM, i.e. the criteria laid down in the global system performance specification (see 2.2). Thus, a convenient way of providing confidence that the technical TLS is being met is by monitoring compliance with the criteria of the global system performance specification (GSPS). If, however, all of the individual GSPS criteria cannot be met, it may then be necessary to consider a trade-off between the parameters as set out in 2.2.5 to 2.2.8. The process is outlined below, and additional technical details are given in Appendix A.

Figure 5-1. Subdivision of CRM parameters from the standpoint of monitoring requirements

Assessment and evaluation of technical height-keeping errors

5.2.5 Monitoring of the first group of parameters identified in 5.2.2 comprises the essential part of system performance monitoring. Since the calculation of risk changes proportionally with these parameters, monitoring procedures must be established to ensure that the following criteria for these parameters are not simultaneously exceeded:

- a) the combination of all passing frequency components has no more of an adverse effect on risk than does a frequency of 0.145 opposite-direction passing events involving horizontal overlap per aircraft flight hour; and
- b) the vertical overlap probability, $P_z(1\ 000)$, does not exceed 1.7×10^{-8} .

If either of these criteria is not satisfied, the collision risk should be reassessed to ensure that the technical TLS is not being exceeded. If criterion b) is not satisfied, remedial action should be taken since this indicates that the RVSM MASPS is not sufficiently effective. If only criterion a) is not satisfied, then a trade-off between vertical overlap probability and the combined frequency of all passing events involving horizontal overlap may be possible as outlined in 2.2.7, provided that the technical TLS is not exceeded. If such a trade-off is not possible, then remedial action should be taken on the frequency of passing events involving horizontal overlap.

5.2.6 In those cases where it is possible to factor the frequency of passing events involving horizontal overlap into a longitudinal and a lateral part, monitoring of the first group of parameters can be performed by ensuring that the following criteria are not simultaneously exceeded:

- a) the vertical overlap probability, $P_z(1\ 000)$, does not exceed 1.7×10^{-8} ;
- b) the combination of all passing frequency components has no more of an adverse effect on risk than does an opposite-direction passing frequency of 2.5 per aircraft flying hour; and
- c) the lateral overlap probability, $P_y(0)$, is not greater than 0.058 (this is based on a lateral path-keeping accuracy standard deviation of 550 m (0.3 NM)).

If any one of these criteria is exceeded, the collision risk probability should be reassessed to ensure that the technical TLS is not being exceeded, and remedial action should be taken.

5.2.7 The assessment of these criteria is considered below, and quantitative details of the trade-off process are provided in Appendix A.

Monitoring of $P_z(1\ 000)$

5.2.8 The assessment of $P_z(1\ 000)$ is a difficult mathematical process. To continually assess whether the value of 1.7×10^{-8} is being exceeded or not, a global height-keeping performance specification (below) has been established. The specification, which must be met for the aggregate of TVE performance in the airspace, is the simultaneous satisfaction of the following four requirements:

- a) the proportion of TVE beyond 90 m (300 ft) in magnitude is less than 2.0×10^{-3} ;
- b) the proportion of TVE beyond 150 m (500 ft) in magnitude is less than 3.5×10^{-6} ;
- c) the proportion of TVE beyond 200 m (650 ft) in magnitude is less than 1.6×10^{-7} ; and

- d) the proportion of TVE between 290 m and 320 m (950 ft and 1 050 ft) in magnitude is less than 1.7×10^{-8} .

5.2.9 From the above, it can be seen that an assessment of TVE is critical to an assessment of $P_2(1\ 000)$. As a result, the accuracy with which TVE can be measured is an important concern. The best overall method of measuring TVE is by comparing the geometric height of an aircraft, as measured by precision radar or some other suitable technology, to the geometric height of its assigned flight level. This accuracy should be such that the mean measurement error is 0 m (0 ft) and the standard deviation of measurement error does not exceed 15 m (50 ft).

5.2.10 Large amounts of TVE data are needed to draw inference from the monitoring process with a high level of confidence, but such large amounts of data may be difficult to obtain. The estimation of TVE through joint assessment of assigned altitude deviation and altimetry system error data may assist in this process. The methodology for the collection and/or calculation of TVE (from component errors) is set out in Appendix A.

Monitoring the frequency of aircraft passing events involving horizontal overlap

5.2.11 The generalized form of the global system performance specification in 2.2.3 requires that the combination of the frequency of all aircraft passing events involving horizontal overlap does not have any more of an adverse effect on risk than does a frequency of 0.145 opposite-direction passing events involving horizontal overlap per aircraft flying hour. This value is the equivalent of the product of the criteria for opposite-direction passing frequency and the lateral overlap probability specified by the original global system performance specification. The background of the latter two criteria is outlined in 5.2.6; however, the generalized form is better suited to crossing traffic and direct routings.

Monitoring aircraft passing frequency

5.2.12 The global system performance specification given in 2.2 requires that the aircraft passing frequency in RVSM airspace does not have any more of an adverse effect on the risk of mid-air collision than does an opposite-direction passing frequency of 2.5 aircraft passings per aircraft flying hour. This passing frequency value was agreed to by the RGCSP, based on an assessment of the annual average passing frequency over the whole airspace of three adjacent area control centres (ACCs) covering the region's busiest traffic flows or highest passing frequency. The use of these adjacent ACCs covering the highest passing frequency was to address the problem of high traffic flows where higher-than-average collision risk may pertain.

5.2.13 ATC authorities must conduct an annual review of either the frequency of aircraft passings involving horizontal overlap or those involving longitudinal overlap, based on traffic movement data from the airspace. Appendix A provides methods of estimating the frequency of these aircraft passings.

Monitoring lateral overlap probability

5.2.14 As part of the process to assess the lateral overlap probability, the RMA should periodically assess lateral path-keeping performance in the airspace concerned. This is due to the fact that, other factors remaining constant, better lateral path-keeping accuracy increases the risk of collision in the event of a loss of a 300 m (1 000 ft) vertical separation. It is also important that planning authorities recognize that the CRM is directly affected by changes in aircraft lateral path-keeping accuracy, and they should appreciate the potential change to risk levels resulting from any mandatory changes, or otherwise, in aircraft navigation equipment. Appendix A provides suggested methods for carrying out this function.

Monitoring other CRM parameters

5.2.15 The remaining CRM parameters are average aircraft speed, relative speed between aircraft, and average aircraft length, width and height within RVSM airspace. As stated previously, either the risk of a mid-air collision is relatively insensitive to these parameter values, or the values are not expected to change substantially. Intensive monitoring of the values of these parameters should not be necessary. The RMA should be aware of their relative importance in the overall process of ensuring that system safety is maintained and should assess their likely values on a periodic basis using whatever means are deemed appropriate. The values of these parameters, as well as all others upon which the global system performance specification is based, are listed in Appendix A.

Other aspects of monitoring the technical performance

5.2.16 It can be seen from the above discussion that the risk due solely to aircraft technical height-keeping performance may be estimated by collecting appropriate data in order to produce values for a number of parameters for use in a collision risk model. This allows for assessments of risk against the TLS to be carried out, thus satisfying the objective of 5.1.2 a). Furthermore, the process, as illustrated, requires that altimetry system error data be collected, and this data can be used to assess the efficacy of the RVSM MASPS and to provide evidence of ASE stability, thus satisfying the objectives at 5.1.2 b) and c). To satisfy the objective of 5.1.3, assessment and evaluation of operational errors are also required and these are covered in section 5.3.

5.2.17 It should be noted that the monitoring requirements, in particular the measurement of TVE, have been established at a stringent level. As a result of these criteria, the data collected and operational experience gained could contribute to some relaxation in the monitoring requirements. For example, if it could be shown that there is no significant correlation between an operator and the technical height-keeping capability of its aircraft, then consideration may be given to the use of TVE data of a specific aircraft type collected in one regional RVSM programme to make an estimate of $P_z(1\ 000)$ in another region, thereby removing the necessity to collect TVE data on all aircraft of that type. Therefore, regional planning groups could or may decide to obtain data from RMAs in regions where TVE is already being calculated to determine the extent of their own monitoring programmes. The requirement to collect data on operational errors and in-flight contingencies to assess the overall risk will still exist because these sorts of errors will be region-specific.

5.3 ASSESSMENT AND EVALUATION OF OPERATIONAL ERRORS AND IN-FLIGHT CONTINGENCIES

5.3.1 In order to meet the monitoring objective as outlined in 5.1.1 b), it will be necessary for the RPG to continually assess and evaluate the impact of RVSM on the risk due to operational errors and in-flight contingencies. The frequency of occurrence of these errors is not considered to be a function of the separation minima applied, as they are common to the total airspace environment and not just restricted to RVSM operations. The RPG should institute such measures as necessary to ensure that the level of collision risk from these causes does not adversely affect the level of safety as measured against the TLS or other agreed upon target. These measures are detailed in 5.4.4 as part of the tasks of the RMA.

5.3.2 The monitoring process will involve the ongoing collection of operational data, and appropriate methodologies will need to be available to process this data to enable comparison with regionally agreed overall safety objectives. The operational data may come from sources such as direct observation, normal operations safety survey (NOSS), line operations safety audits (LOSA), mandatory occurrence reports, air-miss data or near mid-air collision reports and others. RPGs and others concerned with reviewing and acting on these reports should be prepared to take action as necessary. Follow-up activity, in the case of an unacceptable risk increase, should be based on a thorough assessment of the cause of the risk increase and the implementation of mitigating measures if needed. Ongoing

monitoring needs to be carried out to ascertain that the follow-up actions have the required risk-compensation and/or risk-reducing effect.

5.3.3 Details of the assessment of the risk associated with operational errors and in-flight contingencies are provided in Appendix A.

5.4 RESPONSIBILITIES OF THE AUTHORITIES

Introduction

5.4.1 The methodology used to evaluate system performance is described in relation to the specific tasks of the various bodies and units which form a typical regional organization:

- a) regional planning group;
- b) regional monitoring agency; and
- c) air traffic control.

Accountability of the regional planning group (RPG)

5.4.2 The overall accountability for maintaining RVSM system performance rests with the RPG.

5.4.3 Control of the system requires the RPG to conduct an annual review of all aspects of the system's operation. Any review should include:

- a) an assessment of the system safety;
- b) the verification or amendment of the parameters employed in the CRM;
- c) the scrutiny of data and reports from the RMA;
- d) the recommendation of measures to reduce system risk and to improve height-keeping performance; and
- e) the recommendation of improvements to the monitoring process.

Responsibilities of a regional monitoring agency (RMA)

5.4.4 The experience gained through the global monitoring of RVSM operations supports the concept of having an RMA for each region, which has proved to be essential to safety. The RMA has a significant role to play in all aspects of the monitoring process. One of its priorities is to maintain a database of aircraft approved by the respective State authorities for operations at RVSM levels in that region. This is an essential part of the monitoring process because this information is of vital importance if the height-keeping performance data collected by the monitoring systems is to be of use in the risk assessment. RMAs are expected to share database information with other RMAs with specific reference to approvals and height-monitoring data.

5.4.5 Further to 5.4.4, typical duties of an RMA are as follows:

a) to receive reports of those height deviations of non-compliant aircraft which are of a magnitude equal to or greater than the following criteria:

- 1) TVE \geq 90 m (300 ft);
- 2) ASE \geq 75 m (245 ft); and
- 3) AAD \geq 90 m (300 ft);

Note.— The above figures are absolute values and do not include any measurement error in the height-monitoring system employed. The threshold at which follow-up action is initiated should take account of the inherent inaccuracy of the monitoring system.

b) to take necessary action with the relevant State and operator to:

- 1) determine the likely cause of the height deviation; and
- 2) verify the approval status of the relevant operator;

c) to recommend, wherever possible, remedial action;

d) to analyse data to detect height deviation trends and, hence, to take action as in c);

e) to undertake such data collections as required by the RPG to:

- 1) investigate height-keeping performance of the aircraft in the core of the distribution;
- 2) establish or add to a database on the height-keeping performance of:
 - i) the aircraft population;
 - ii) aircraft types or categories; and
 - iii) individual airframes;

f) to monitor the level of risk of collision as a consequence of operational errors and in-flight contingencies as follows:

- 1) establish a mechanism for collation and analysis of all reports of height deviations of 90 m (300 ft) or more resulting from the above errors/actions;
- 2) determine, wherever possible, the root cause of each deviation together with its size and duration;
- 3) calculate the frequency of occurrence;
- 4) assess the overall risk (technical combined with operational and in-flight contingencies) in the system against the overall safety objectives (see 2.1); and
- 5) initiate remedial action as required;

Note.— It is important to bear in mind that height deviations, as a consequence of operational errors and in-flight contingencies, occur in all airspace irrespective of the separation minimum. The purpose of maintaining this monitoring activity is to ensure that operations in RVSM airspace do not induce an increase in the risk of collision from these causes and that the total vertical risk does not exceed the agreed overall safety objectives (see 2.1). The actions/measures proposed to reduce risk should not be exclusive to RVSM airspace.

- g) to initiate checks on the “approval status” of aircraft operating in the relevant RVSM airspace (see 3.3.3 to 3.3.6), identify non-approved operators and aircraft using RVSM airspace and notify the appropriate State of Registry/State of the Operator accordingly;
- h) to circulate regular reports on all height-keeping deviations, together with such graphs and tables necessary to relate the estimated system risk to the TLS, employing the criteria detailed in 5.2.8, for which formats are suggested in Appendix A; and
- i) to submit annual reports to the RPG.

Responsibilities of State regulatory authorities in the monitoring process

5.4.6 As part of the process to monitor compliance with the global system performance and global height-keeping performance, independent monitoring of aircraft height-keeping performance in a given region may be instigated. The RMA will be responsible for collating and analysing the height-keeping data and, in the event that an RVSM-approved aircraft is monitored with an estimated ASE or TVE in excess of the limits, corrected for system measurement inaccuracy, set out at 5.4.5, will take action to inform both the appropriate State authority and the operator. The State authority will be requested to take action to help the RMA determine the cause of the error. In the event that the investigation reaches an unsatisfactory conclusion, the State authority may consider suspending or revoking the operator's RVSM approval. Following any rectification work, the operator would again be expected to demonstrate compliance with the RVSM MASPS by ensuring that the subject aircraft has been monitored by an independent height-monitoring system at the earliest opportunity.

Role of the appropriate ATC authority in monitoring height-keeping performance

5.4.7 The ATC authority has a vital role to play in the monitoring process in that there is a need to gather information on and report any deviation equal to or greater than 90 m (300 ft), **for any reason**, from cleared levels whether the deviation causes an incident or not. This information will contribute to the assessment of the level of overall risk in the system. The information required by the RMA to conduct the risk assessment might, depending on the region of implementation, include the following data:

- a) reporting unit;
- b) location of deviation, either as latitude/longitude or a bearing and distance from a significant point;
- c) date and time of large height deviation;
- d) sub-portion of airspace, such as established route system, if applicable;
- e) flight identification and aircraft type;
- f) assigned flight level;

- g) final reported flight level or altitude and basis for establishment (e.g. pilot report or Mode C);
 - h) duration at incorrect level or altitude;
 - i) possible cause of deviation;
 - j) any other traffic in potential conflict during deviation;
 - k) crew comments when notified of deviation; and
 - l) remarks from ATC unit making report.
-

Appendix A

QUANTITATIVE ASPECTS OF SYSTEM PERFORMANCE MONITORING

1. INTRODUCTION

1.1 This appendix provides guidance concerning the quantitative aspects of independent system performance monitoring associated with RVSM operations. It includes the assembly, treatment and use of data necessary to demonstrate that compliance with the global system performance specification in Chapter 2, 2.2, is satisfactory. Extensive information is presented on the vertical overlap probability, $P_z(1\ 000)$. This appendix also presents a height-keeping performance verification process for RVSM operations and contains an example that illustrates calculations of sample-size requirements associated with the safety assessment in a hypothetical region.

1.2 More details on the material in this appendix can be found in regional guidance material, such as the Supplement to NAT Doc 002 on risk assessment and monitoring aspects in the context of NAT RVSM.

1.3 It is important to note that while the guidance in this appendix focuses primarily on the assessment of risk due to technical height-keeping deviations, consideration should also be given to the risk due to operational errors and in-flight contingencies. Information on this aspect is given in Section 5 of this appendix.

2. COLLISION RISK ASSESSMENT

Introduction

2.1 The use of analytical methods to guide decision-makers on the safety of an activity is generally referred to as risk assessment. Such an assessment consists of two elements: risk estimation and risk evaluation. Risk estimation refers to the process of determining the expected level of risk that will result from the activity or proposal under consideration. Risk evaluation refers to the process of deciding whether such a level of risk is acceptable.

2.2 The term risk is used to represent a numerical index of safety. When applied to any particular problem, a formal definition of risk requires specification of the units in which it will be measured. For the purpose of collision risk assessment, the units adopted here are fatal accidents per aircraft flight hour.

2.3 The risk estimation method consists of using a CRM, which expresses the risk of a mid-air collision in an airspace in terms of a number of quantifiable parameters. The risk evaluation method consists of determining that level of risk which is deemed acceptable, termed the target level of safety (TLS). It is against the TLS that the estimated risk can be compared, providing a quantitative basis for judging the safety of operations in an airspace.

The collision risk model

2.4 The risk of collision to be modelled is that due to the loss of procedural vertical separation between aircraft flying between FL 290 and FL 410 inclusive in a given portion of an airspace. One collision between two aircraft is

counted as the occurrence of two accidents. The risk of collision depends both on the total number and types of aircraft flying in the system and the system characteristics.

2.5 The CRM provides an estimate of the number of accidents within an airspace system that might occur per aircraft flight hour due to aircraft collisions resulting from the loss of procedural vertical separation in an RVSM environment.

2.6 The basic model, which can be applied equivalently to vertical, lateral and longitudinal separation analysis, is expressed in terms of quantifiable parameters. In the vertical dimension the CRM can be broken down in order to separately model a single route on which aircraft are flying in the same or opposite directions at adjacent flight levels, pairs of crossing routes and combinations of individual and intersecting routes.

2.7 Three parameters used within the basic model: the vertical overlap probability, denoted as $P_z(1\ 000)$; the lateral overlap probability, denoted as $P_y(0)$; and the aircraft passing frequency, are the most important quantities in determining the vertical collision risk. Of these, the vertical overlap probability is the most difficult to estimate.

2.8 The global system performance specification stated in Chapter 2, 2.2, limits the maximum values associated with each of these parameters to ensure an acceptable level of collision risk due to the loss of procedural vertical separation throughout worldwide airspace. The global height-keeping performance specification stated in Chapter 2, 2.3, presents requirements for the height-keeping performance necessary to satisfy the $P_z(1\ 000)$ of the global system performance specification.

2.9 For crossing traffic and “direct-to” clearances, the generalized form of the global system performance specification stated in 2.2.3 is more appropriate. This form limits the maximum values for the vertical overlap probability and the frequency of aircraft passages involving horizontal overlap to ensure an acceptable level of collision risk due to the loss of procedural vertical separation throughout worldwide airspace.

2.10 Section 3 of this appendix discusses the monitoring of the lateral overlap probability and the aircraft passing frequency. Section 4 outlines possible methods for monitoring the vertical overlap probability and assessing whether the associated height-keeping performance specification is being met.

2.11 The remaining CRM parameters are not expected to change substantially over time. Nevertheless, RMAs should be aware, as noted in 5.2.15, of their relative importance in the overall risk assessment process and should assess their likely values on a periodic basis. The collision risk parameter values used to derive the value of $P_z(1\ 000)$ of 1.7×10^{-8} necessary to meet the safety goal for RVSM technical risk (see Chapter 2, 2.1) are presented in Table A-1.

The target level of safety

2.12 The TLS represents the acceptable level of risk appropriate to the decision under consideration. In aviation the TLS is expressed in units of fatal accidents per aircraft flight hour, since the number rather than the individual severity of fatal accidents is what decision-makers can hope to control through the choice of separation standard values.

2.13 The RGCSP chose a TLS value of 2.5×10^{-9} fatal accidents per aircraft flight hour as the upper limit “attributable to the loss of procedural vertical separation” to guide the development of the global system performance specification.

Note.— The TLS of 2.5×10^{-9} fatal accidents per aircraft flight hour applies only to technical height-keeping errors.

Table A-1. Parameter values used to define the global height-keeping performance specification

<i>Description</i>	<i>Value/unit</i>
Lateral path-keeping standard deviation (s_y)	550 m (0.3 NM)
Lateral overlap probability ($P_y(0)$)	0.058
Opposite-direction passing frequency ($N_x(\text{opp})$)	2.5 aircraft passings/hour
Same-direction passing frequency ($N_x(\text{same})$)	0 aircraft passings/hour
Crossing passing frequency ($N_{xy}(\text{cross})$)	0 aircraft passings/hour
Average aircraft length (λ_x)	45 m (148 ft)
Average aircraft width (λ_y)	45 m (148 ft)
Average aircraft height (λ_z)	15 m (50 ft)
Average relative same-direction aircraft speed ($ \Delta V $)	37 km/h (20 kt)
Average aircraft speed ($ V $)	870 km/h (470 kt)
Average relative cross-track aircraft speed ($ y $)	7 km/h (4 kt)
Average relative vertical aircraft speed during loss of vertical separation ($ z $)	19 km/h (10 kt)

3. MONITORING AIRCRAFT PASSING FREQUENCY AND LATERAL NAVIGATION PERFORMANCE

3.1 Ensuring that the aircraft passing frequency and lateral navigational performance in an airspace are consistent with the global system performance specification is an ongoing requirement for monitoring safety in an RVSM airspace. Monitoring parameters are reflected in Chapter 5 of this manual. The following presents procedures for estimating and testing the parameters in accordance with these requirements.

Monitoring passing frequency

Introduction

3.2 The proportion of time during which aircraft at adjacent flight levels are exposed to the risk of collision due to the loss of procedural vertical separation is accounted for in the global system performance specification by defining a maximum frequency of opposite-direction passings of aircraft on the same route. This value, 2.5 passings per aircraft flight hour, was chosen to accommodate growth in global traffic over the planning horizon set in this manual. In practice, exposure may occur due to aircraft passings in the same or opposite directions on the same route at adjacent flight levels or due to passings of aircraft at adjacent flight levels on separate routes at a crossing point. (A closely related parameter often used in oceanic track systems is “occupancy,” which is a measure of the number of aircraft at adjacent flight levels within a specified distance of a typical aircraft.) Independent system performance monitoring requires that the combined effect of the frequency of these various types of passings be estimated using traffic movement data from RVSM airspace. This should be compared to 2.5 opposite-direction aircraft passings per flight hour. These estimates should be determined over the whole airspace being assessed if practical to do so. If the airspace covers a regional area, then the airspace of three adjacent ACCs covering that region’s busiest traffic flows or highest passing frequency should be assessed, in order to address the problem of high traffic flows where higher-than-average collision risk may pertain.

3.3 The overall approach to estimating the frequency of the various types of aircraft passings is presented in 3.4 to 3.13 below. Procedures for comparing the combined effect of the estimated frequency to that used in developing the global height-keeping performance specification are presented in 3.14 to 3.19 below.

Estimating aircraft passing frequency

Data required

3.4 Aircraft flight data are necessary to estimate the passing frequency (or occupancy, where appropriate). The data should reflect the range of traffic flows in RVSM airspace consistent with the requirements of Chapter 2, 2.2, occasioned by daily, weekly and seasonal fluctuations in demand. Such sampling has been accomplished in practice by choosing a specific date or week of the month and gathering traffic movement data (actual or simulated) at that time for a year.

Types of data

3.5 Data used to determine aircraft passing frequencies involving horizontal overlap may be sourced from paper flight progress strips or from automated systems using inputs from ATS surveillance systems. The basic principle is to calculate the total number of passing events, multiplying by 2 and dividing by the total number of flight hours between FL 290 and FL 410 inclusive, in straight and level flight.

3.6 The following time- and flow-related data should be obtained for each ACC en-route sector relative to the airspace being assessed:

- a) the time during which ATS surveillance system tracks were recorded;
- b) the total number of aircraft within the sector;
- c) the flow rate (per hour at each flight level) across the sector boundary;
- d) the total number of flight hours in level flight, classified by nearest flight level; and
- e) the total number of flight hours in climb/descent, classified by adjacent flight levels.

Estimating the passing frequency of aircraft on same- and opposite-direction routes

3.7 All routes within the airspace being assessed should be examined on an individual basis when estimating aircraft passing frequency or occupancy. If this is not practical, care should be taken that the routes analysed provide representative estimates. Each route should be divided into segments, for example, by reporting points or navigation aid locations. The traffic movement data, organized by flight level on each segment, must then be examined either manually or automatically to determine the number of pairs of aircraft at adjacent flight levels that pass each other in the same or in opposite directions. The number of same- and opposite-direction aircraft passings should then be combined with similar counts from all other route segments analysed. The sum of the overall same- and opposite-direction aircraft passings should then be multiplied by 2 and divided by the total number of flight hours between FL 290 and FL 410 inclusive, in straight and level flight on the segments during the periods analysed, giving the same- and opposite-direction aircraft passing frequency estimates. If occupancy analysis is deemed appropriate, vertical occupancy can be estimated in a manner analogous to that for estimating lateral occupancy shown in the *Air Traffic Services Planning Manual* (Doc 9426), Part II, Section 2, Chapter 4, Appendix C.

Estimating aircraft passing frequency on crossing routes

3.8 After identifying crossing routes within the airspace being assessed, the aircraft passing frequency at all the crossing points should be estimated. If this is not practical, care should be taken that the crossings analysed provide representative estimates. The number of aircraft pairs involving horizontal overlap at crossing points should be counted, multiplied by 2 and divided by the total flight time in the sampled RVSM airspace to produce an estimate of the crossing passing frequency.

3.9 Aircraft passings involving horizontal overlap at route crossing points are rare events and their frequency is difficult to measure. Nonetheless, it is possible to estimate this frequency; traffic flows representative of crossing routes may be used in a model similar to that which is presented in Doc 9426.

3.10 In busy continental airspace, flights are generally under ATS system surveillance and subject to tactical control by ATC. This leads to highly complex and, frequently, very variable traffic patterns with the actual tracks flown often deviating from the published ATS routes and crossing at a variety of angles. As a result, it is not possible to accurately estimate a frequency of passing events based only on the information on traffic flows on the ATS routes.

3.11 A realistic picture of the actual traffic patterns can be obtained from ATS surveillance system data. From this data it can be determined first of all whether a pair of aircraft passes within a specified volume of airspace. If this is the case, it contributes to the frequency of such passing events in the airspace considered. The actual relative velocity can also be estimated from the ATS surveillance system data. This information can then be processed in a way similar to that for an airspace with crossing routes.

3.12 Like aircraft passing events involving horizontal overlap at crossing points, passing events for direct routings involving horizontal overlap are rare events and difficult to estimate. The problem can be addressed by suitably defining vertical proximate events.

Checking aircraft passing frequency

3.13 An airspace consisting of a route structure without crossing routes may be checked by plotting the estimated values for same- and opposite-direction aircraft passing frequency ($N_x(\text{same})$ and $N_x(\text{opp})$) in Figure A-1. If these values are within the shaded area, then the airspace under consideration contains a frequency that affects risks no more than that used in developing the global height-keeping performance specification defined in Chapter 2, 2.3, of this manual. If the values are outside the shaded area, then a trade-off between the parameters of the global system performance specification may be possible as introduced in 2.2.5 to 2.2.8 and further explained in the next paragraphs. If the trade-off is not feasible, then the aircraft passing frequency in the airspace is too high to meet the technical safety objectives, and the RPG may need to consider employing either some form of air traffic management or airspace restructuring.

3.14 Assuming that the probability of vertical overlap, $P_z(1\ 000)$, is equal to 1.7×10^{-8} , the first type of trade-off to be considered is that between the passing frequency and the lateral navigation performance (see Figure A-2). This requires an estimate of the probability of lateral overlap, $P_y(0)$, to be known and to be less than a value of 0.058 corresponding with a standard deviation of lateral path-keeping error of 550 m (0.3 NM). If the estimate of the probability of lateral overlap is larger than the value of 0.058, then this type of trade-off is not possible. If the estimate of the probability of lateral overlap is less than the value of 0.058, then the check on the combined effect of same- and opposite-direction passing frequency is given by the following inequality:

$$N_x(\text{opp}) + \frac{2.5}{0.96} N_x(\text{same}) \leq \left(\frac{0.058}{P_y(0)} \right) 2.5 \quad (1)$$

where $P_y(0)$ represents the estimate of the probability of lateral overlap. Figure A-3 shows the region of acceptable same- and opposite-direction passing frequency for two values of $P_y(0)$, namely $P_y(0) = 0.058$ and $P_y(0) = 0.029$. The former value just meets the pertinent requirement of the global system performance specification of 2.2.2 b) of this manual and reproduces the result of Figure A-1. The other value is half of the former and represents a twice as large standard deviation of lateral path-keeping error. Figure A-2 shows that combinations of larger passing frequency values are allowed then.

Note.— The product of the numbers in the right-hand side of the inequality (1) represents 0.145 opposite-direction passing events involving horizontal overlap (see 2.2.3 of this manual).

3.15 If the estimated values for same- and opposite-direction passing frequency are within the larger area of Figure A-3, then the trade-off has been successful. If the estimated values are outside the enlarged area, then a different trade-off may be possible, i.e. between the parameters in the horizontal domain and the vertical domain as set out in 2.2.7 of this manual. The check on the combined effect of same- and opposite-direction passing frequency is then given by the inequality:

$$N_x(opp) + \frac{2.5}{0.96} N_x(same) \leq \left(\frac{0.058}{P_y(0)}\right) \left(\frac{1.7 \times 10^{-8}}{P_z(1000)}\right) 2.5 \tag{2}$$

3.16 For airspace that contains crossing routes, a conservative check was developed by considering crossing angles and aircraft velocities. It involves determining if the combined frequency of all passing events within the airspace meets the following equation:

$$\frac{2.5}{0.96} N_x(same) + N_x(opp) + 37.5 N_{xy}(cross) \leq 2.5 \tag{3}$$

Figure A-1. Region of acceptable aircraft passing frequency for same- and opposite-direction traffic

Figure A-2. Flow diagram of the trade-off between global system performance specification parameters for same- and opposite-direction traffic when $P_y(0) \leq 0.058$ and on the assumption that $P_z(1\ 000) \leq 1.7 \times 10^{-8}$

Figure A-3. Region of acceptable aircraft passing frequency for same- and opposite-direction traffic based on a trade-off with a probability of lateral overlap, $P_y(0)$, for two different values of $P_y(0)$

Note.— Outline only, not to scale.

3.17 A somewhat less conservative check is applicable when the minimum crossing angle is not smaller than 10 degrees, namely:

$$\frac{2.5}{0.96}N_x(\text{same}) + N_x(\text{opp}) + 21.4N_{xy}(\text{cross}) \leq 2.5 \quad (4)$$

3.18 If the left-hand side of equation (3) or (4) is less than or equal to 2.5, the check has been successful and the aircraft passing frequency within the airspace being assessed is at or below the equivalent value used to develop the global height-keeping performance specification. If the left side of equation (3) or (4) is greater than 2.5, the check has been unsuccessful. This latter condition implies that either the aircraft passing frequency in the airspace is too high to meet the specification or its combination of crossing angles or aircraft velocities are outside the ranges considered in developing the check for inequality. If this situation applies, aircraft passing frequency may be calculated using model parameters from the respective airspace. The above inequality may also be used in place of Figure A-1 when there are no crossing routes by setting $N_{xy}(\text{cross})$ to zero.

Monitoring lateral navigational performance

3.19 As lateral navigational performance in an airspace improves, the risk of collision due to the loss of procedural vertical separation increases. This paradoxical effect requires that actual lateral path-keeping performance in RVSM airspace be examined to ensure that assumptions made in developing the global height-keeping performance specification are not violated.

3.20 Lateral navigational performance influences determination of the global height-keeping performance specification through the standard deviation of lateral path-keeping. Assuming a first Laplace distribution of lateral path-keeping, the lateral overlap probability, $P_y(0)$, may be represented symbolically as:

$$P_y(0) = \lambda_y / (\sigma_y \sqrt{2}) \quad (5)$$

where λ_y is the average aircraft width and σ_y is the standard deviation of lateral path-keeping. As shown in Table A-1, a standard deviation of 550 m (0.3 NM) representing a population of aircraft all equipped with a similar precision area navigation (RNAV) system has been assumed.

3.21 When different types of navigation systems are present, an estimate of the overall variance is obtained by weighting the individual variances with the proportions of aircraft equipped with each type of navigation system. To check that a lateral navigation performance is straightforward: the estimated standard deviation value should be greater than that used to develop the global height-keeping performance specification (i.e. 550 m (0.3 NM)).

3.22 If the check on the standard deviation is negative, then it may be possible to trade off the better lateral navigation performance against a passing frequency which is lower than that assumed in the development of the global system performance specification (see Figure A-4). On the assumption that the probability of vertical overlap, $P_z(1\ 000)$, is equal to 1.7×10^{-8} , the trade-off as set out in 2.2.6 of this manual is obtained by inverting equation (1), i.e.:

$$\frac{P_y(0)}{0.058} \leq \frac{2.5}{N_x(\text{opp}) + \frac{2.73}{1.04}N_x(\text{same})} \quad (6)$$

The denominator in the right-hand side of equation (6) will be smaller than the value of 2.5 if the combined passing frequency of all aircraft passing events is within the acceptable area of Figure A-1. The right-hand side will then be

greater than one (1), which defines the margin by which $P_y(0)$ may exceed its original bound of 0.058, without being inconsistent with the horizontal part of the global system performance specification. The margin on $P_y(0)$ can be directly translated into a margin on the standard deviation σ_y of the lateral path-keeping error distribution by means of equation (5).

Figure A-4. Flow diagram of the trade-off between global system performance specification parameters for same- and opposite-direction traffic when the combination of same- and opposite- direction passing frequency is within the shaded area of Figure A-1 and on the assumption that $P_z(1\ 000) \leq 1.7 \times 10^{-8}$

3.23 If the trade-off in 2.2.6 of this manual is not possible, it may finally be examined whether a trade-off between the vertical and horizontal domains as set out in 2.2.7 is feasible. Thus, on the assumption that the probability of vertical overlap, $P_z(1\ 000)$, is well below the value of 1.7×10^{-8} , the trade-off is obtained by inverting equation (2), i.e.:

$$\frac{P_y(0)}{0.058} \leq \left(\frac{1.7 \times 10^{-8}}{P_z(1000)} \right) \frac{2.5}{N_x(opp) + \frac{2.5}{1.96} N_x(same)} \quad (7)$$

3.24 The first ratio in the right-hand side of equation (7) provides the margin due to $P_z(1\ 000)$ being well below the bound of 1.7×10^{-8} , for example 1.7×10^{-9} . This ratio then results in a factor of 10. The resulting margin for $P_y(0)$ is dependent on the value of the passing frequency as shown by the second ratio in the right-hand side of equation (7). If the estimated values of the two passing frequency components are within the allowable area of Figure A-1, then this provides some additional margin (which in itself is insufficient to cover the higher lateral navigation performance as described for the first type of trade-off in 3.20). If the estimated values of the two passing frequency components are outside the allowable area of Figure A-1, then the second ratio is less than one and takes up part (or all) of the margin provided by the vertical dimension (this will already have been found independently in the check on passing frequency, cf. 3.12 to 3.14). Thus, the ultimate margin for $P_y(0)$ is given by the full right-hand side of equation (7).

3.25 The trade-offs illustrated in the Figures A-3 and A-4 can be combined into a single diagram as shown in Figure A-5. Note that an additional branch is present for the case where $N_x(\text{same})$ and $N_x(\text{opp})$ are not within the shaded area of Figure A-1 and $P_y(0)$ is not less than or equal to 0.058. In that case, the trade-off in 2.2.7 of this manual between the probability of vertical overlap and the airspace parameters may still be possible. The corresponding trade-off equation is given by:

$$P_y(0) \leq \left\{ N_x(\text{opp}) + \frac{2.5}{0.96} N_x(\text{same}) \right\} \tag{8}$$

$$\left(\frac{1.7 \times 10^{-8}}{P_z(1000)} \right) (0.058)(2.5)$$

Figure A-5. Flow diagram of the trade-off between global system performance specification parameters for same- and opposite-direction traffic on the assumption that $P_z(1\ 000) \leq 1.7 \times 10^{-8}$

Application of the checking process to airspace studied by the RGCSP

3.26 Airspace studied by the RGCSP was examined to provide examples of the application of the checking process. The standard deviations of lateral path-keeping and values for the aircraft passing frequency are taken from the report of the RGCSP/6 Meeting.

3.27 As an example of an airspace dominated by parallel routes, the values for the aircraft passing frequency estimated for NAT airspace are plotted in Figure A-6 and are seen to be well within the acceptable area. Values for same- and opposite-direction aircraft passing frequency for European, Japanese and United States airspace are also plotted in the figure.

3.28 The application of the checking process to airspace with crossing routes is based on equation (3). As an example, European airspace values are used. Substituting these passing frequency values, the left-hand side of equation (3) is 0.575. Because this value is less than 2.5, the inequality is maintained and the combination of the frequency of en-route and crossing-route aircraft passings is within the bounds anticipated when developing the global height-keeping performance specification.

4. MONITORING HEIGHT-KEEPING PERFORMANCE

Introduction

4.1 This section first outlines methods for measuring TVE through a comparison of the geometric height of an aircraft tracked by height monitoring units (HMUs), or by GPS-based monitoring unit (GMU) height monitoring systems (GMS), against the geometric height of the assigned flight level, and secondly for estimating TVE through estimation of its altimetry system error (ASE) and assigned altitude deviation (AAD) components, where AAD is a surrogate for flight technical error (FTE). Because the rate of collection of measured TVE data is likely to be relatively low, estimated TVE will be of value in increasing the size of the data sample and affording greater statistical confidence that the global

height-keeping performance specification has been met. It is important to note, however, that the component error methodology for estimating TVE is dependent upon the availability of measured TVE from which to derive a value for ASE.

Note.— With the advance in surveillance technology (such as ADS-B) and the accompanying ability to use this technology for height-keeping monitoring, this section will be amended so as to include such technological advances, as appropriate.

General approach

4.2 A four-element approach for the collection and assessment of height-keeping performance data in the verification phase is proposed in the following four paragraphs. This approach may allow the RPG to gain a growing statistical confidence in meeting the safety and monitoring objectives throughout the verification phase. The four elements will be conducted simultaneously with each stage building one upon the other. In the first step, examining typical performance will include estimating ASE values. Those aircraft with marginally acceptable ASEs (aberrant aircraft) or those that develop large values (non-compliant aircraft) are of major concern since the presence of a small number of such aircraft would degrade system safety. The second element of the process consists of conducting an ASE census in order to examine and eliminate, with a high degree of confidence, any excessive ASE. The third element counts the number of large errors that directly affect risk and provides the associated confidence level for the target levels of safety. Finally, the process involves determining if the global height-keeping performance specification has been met.

4.3 The first element of the data evaluation consists of examining the typical height-keeping performance of aircraft, with a given level of confidence, by identifying the number of TVE, ASE and AAD values beyond the tolerance limits given in Chapter 5, 5.4.5, and counting the number of occurrences of each value. In addition, height-keeping performance should be examined in order to detect adverse trends that could ultimately result in unacceptable performance. This examination will focus on performance exhibited by individual aircraft types and operators, with analysis of mean TVE, ASE, and AAD performance and variability about the means. This examination should be repeated periodically throughout the four-element process.

4.4 The second element of the four-element process consists of conducting the ASE census. It will, of course, take a longer time to complete than the first element since its primary goal is to obtain estimates of the ASE of every aircraft and to identify those that exceed the ASE tolerance limit of 5.4.5 a) so that follow-up corrective action can be taken. When such a census cannot be conducted, it is necessary to obtain a representative sample which, at a minimum, contains a census of the RVSM MASPS-approved aircraft types and data on every combination of aircraft/operator pairing. For example, in the NAT RVSM programme, somewhere in the order of 80 per cent of the predicted population was monitored as part of the verification phase. On the basis of the quality of the collected data, it was adjudged to be representative of the population. A suggested approach to dealing with the collected ASE data is described in this appendix.

4.5 The third element of the quantitative evaluation consists of providing an indication of the currently achieved level of safety and the level of confidence that is being attained within the system. Risk estimation based on probability distribution fitting and/or control charts for critically large ASEs, TVEs and AADs, similar to those described for typical height-keeping performance, will be applied. This element should also include an evaluation of the level of risk caused by operational errors and emergency actions.

4.6 The objective of the fourth element is to demonstrate compliance with the global height-keeping performance specification. This objective will continue to be pursued after the introduction of RVSM.

TVE component errors

Introduction

4.7 The TVE of an aircraft is taken to be the result of the statistically independent and additive contributions of contemporaneous errors in the aircraft's altimetry and altitude-keeping systems. These two component errors of TVE are considered to have different characteristics.

4.8 Estimation of the ASE and AAD of an aircraft is possible during independent system performance monitoring operations. These component error estimates are necessary in order to support the risk-reduction goal of monitoring so that any observed instances of large TVE can be classified in regard to the height-keeping subsystem which is likely to be at fault.

Estimation of ASE

4.9 The ASE of an aircraft is expected to vary within some limits about some mean value which is characteristic for each individual aircraft for a given set of operating conditions. This characteristic mean is expected to be largely invariant over many flights, unless there is some intervention, such as damage or repair, which changes the error characteristics. The interval, over which ASE remains relatively constant, in the absence of intervention, is not precisely known, but data and experience do indicate some moderate increase in the magnitude of ASE as an altimetry system ages. Data and experience also indicate that the errors of the independent altimetry systems of the pilot and co-pilot are not necessarily equal.

4.10 An aircraft's actual ASE at any time is the difference between its actual TVE and contemporaneous actual FTE. Given a measure of TVE and a contemporaneous AAD for the aircraft, the difference between TVE and AAD provides an estimate of ASE. The accuracy of this estimate is affected by the granularity of the 30-m (100-ft) quantization inherent in Mode C and any correspondence error between the Mode C return and the altitude display. When averaged over a number of repeated samples, however, this approach should enable a representative value of ASE to be established.

Estimation of AAD

4.11 Errors in altitude-keeping can vary during a single aircraft flight. Data on altitude-keeping errors from such sources as flight data recorders and secondary surveillance radar (SSR) systems indicate that magnitudes of less than 15 m (50 ft) predominate but that, on relatively infrequent occasions, error magnitudes of 90 m (300 ft) or more occur. These latter error magnitudes typically persist for short periods, in the order of 30 to 180 seconds. There are two approaches to estimating the performance of altitude-keeping systems. If either direct altimeter readings or flight data recorder information on pressure altitude as measured by the altimetry system are used, the difference between this altitude and the aircraft's cleared flight level is termed FTE. If SSR returns are used, the difference between a transponded Mode C reading and a cleared flight level is AAD.

4.12 Where available and practicable within RVSM airspace, SSR Mode C data should be gathered. Typically, a Mode C altitude return will be available every 4 to 12 seconds if a single SSR is tracking an aircraft. Each such return provides an estimate of AAD for the aircraft when CFL is subtracted. These AAD estimates will not be statistically independent but will provide the opportunity to observe larger altitude-keeping system errors that may occur. Consideration should also be given to the inclusion of large FTEs (due to turbulence, autopilot failures, etc.) that might be documented in occurrence reports.

Procedures for monitoring height-keeping performance

Introduction

4.13 Independent system performance monitoring requires the measurement of aircraft height-keeping errors. Direct measurement of TVE for an aircraft can, at present, be carried out only by measuring the aircraft's geometric height at a given time and estimating the contemporaneous and collocated geometric height of the flight level to which it is assigned. The difference between these two heights yields the TVE measurement.

4.14 Given the nature of the TVE component errors, independent system performance monitoring should consist of an integrated set of procedures for:

- a) monitoring TVE, with a system having error characteristics identified in 4.21 below, in the airspace so as to obtain as broadly based a sample of aircraft types and users as is practicable;
- b) monitoring AAD through Mode C coverage; and
- c) producing a companion ASE estimate for each TVE measure.

4.15 In order to ensure the maintenance of the level of safety within RVSM airspace, it will be necessary to collect representative AAD data which, combined with the aforementioned TVE data, would be used in the estimation of P_z (1 000).

Measurement accuracy for TVE

4.16 States contributing TVE estimates to RGCSP deliberations independently determined that the combined standard deviation of measurement error for both the aircraft and the flight level geometric heights should not be greater than 15 m (50 ft). The individual mean measurement error for the aircraft and the flight level geometric heights should be 0 m (0 ft). These measurement error criteria should also be taken as applicable to any system performance monitoring programme. Characteristics of a height-monitoring system are described in 4.21.

Aberrant and non-compliant aircraft

4.17 The criteria for non-compliant aircraft to be applied by an RMA are:

- a) $TVE \geq 90$ m (300 ft);
- b) $ASE \geq 75$ m (245 ft); and
- c) $AAD \geq 90$ m (300 ft).

In deciding whether or not an aircraft meets these criteria, the inherent inaccuracy (measurement error) of the monitoring system, as well as normal variation in an airframe's ASE or TVE, needs to be taken into account. The decision process is affected by two types of statistical error: type I error and type II error. To avoid unjustified action being initiated on the basis of a large measured deviation (type I error), the trigger levels for action are to be set at slightly larger values than the criteria above. An airframe is deemed to be non-compliant if any of its monitored deviations exceed these trigger levels. However, the situation also needs to be avoided where an aircraft that does not meet the above criteria is labelled as meeting the criteria (type II error). To ensure this, the trigger levels for action are to be set at slightly lower values than the above set of trigger levels. An aircraft whose measured height-keeping deviations exceed any of the

lower trigger levels is called aberrant. Aberrant aircraft, thus, are those aircraft which exhibit measured height-keeping performance that is significantly different from the core height-keeping performance measured for the whole population.

4.18 As an example, the sets of trigger levels currently in use are shown below:

- a) trigger levels for aberrant aircraft: $|ASE| \geq 49$ m (160 ft) or $|TVE| \geq 52$ m (170 ft); and
- b) trigger levels for non-compliant aircraft: $|ASE| \geq 90$ m (300 ft) or $|TVE| \geq 107$ m (350 ft) or $|AAD| \geq 90$ m (300 ft).

Since determination of these trigger values is dependent on an evaluation of the measurement accuracy of the monitoring system and also the height-keeping performance of the whole regional population, the trigger levels will be subject to change.

Monitoring strategy for TVE/ASE

4.19 Because of the nature of some of the specialized systems required, TVE may be able to be monitored in limited portions of an airspace only. Thus in those circumstances, TVE monitoring should be planned and conducted so that as broad a cross-section as possible of the user population and aircraft types can be observed. TVE monitoring can be used to uncover instances of larger ASE not detectable by other means.

Monitoring strategy for AAD

4.20 Because of the generally short duration of large AADs, this component error should be monitored, to the extent practicable, wherever there is ATS surveillance coverage in RVSM airspace. The actual monitoring process, however, should record only instances of AAD magnitudes of 90 m (300 ft) or more for both risk reduction, by means of error follow-up, and risk assessment. To conduct risk assessment, it will also be necessary to estimate the total amount of level-flight flying time in the ATS surveillance coverage area at and above FL 290 to FL 410 inclusive. With the count of larger AAD errors and the total flying time, an estimate of the proportion of time during which larger AAD errors occur can be made.

Characteristics of a height-monitoring system

4.21 The basic purpose of a height-monitoring system is to collect data on the technical height-keeping performance of aircraft in straight and level flight between FL 290 and FL 410 inclusive. The following features form the basis of the operational requirement for such a system:

- a) it should be capable of automatic operation where practicable;
- b) it should be capable of measuring the geometric height of aircraft in straight and level flight between FL 290 and FL 410 inclusive over a period of 30 seconds or more;
- c) it should be capable of accepting input data on the estimated geometric height of the usable flight levels between FL 290 and FL 410 inclusive;
- d) it should record the geometric height of the aircraft and the flight level;
- e) it should be able to access aircraft identification and Mode C SSR readings during the TVE tracking period;

- f) it should be capable of deriving TVE, AAD and ASE;
- g) it should be capable of flagging “alerts” when a predetermined TVE, ASE or AAD has been exceeded, and this information should be in such a format so as to be readily identifiable during the initial scrutiny of the data; and
- h) it should record all data in a format that facilitates subsequent analysis.

Risk reduction using observed height-keeping performance data

4.22 In addition to taking investigative action on aircraft with observations of height-keeping performance not considered to be in compliance with the RVSM MASPS, each observed instance of aberrant TVE, AAD or ASE should also be the subject of follow-up investigation. Errors of large magnitudes should be rare events in the light of requirements on the component systems stipulated in Chapter 3. It is important that records of these larger errors be analysed as a group to look for systematic causes of deviations and for adverse trends in the component errors. When such causes are identified, they should be the object of appropriate remedial actions (affecting, for example, the maintenance practices of all users with a particular type of altimetry system if existing practices are implicated in the causes of a systematically occurring large altimetry system error). If the cause of a specific larger error can be judged to have been removed, it may be reasonable to conduct subsequent risk assessment with observed instances of the error type removed from the monitoring results.

Note.— The values of aberrant TVEs, AADs or ASEs should be determined based on typical performance of the population as a whole and should also allow for measurement error of the height-monitoring system employed.

Composition of TVE samples

4.23 The composition of the TVE sample used for risk assessment is important. Because the ASE component of TVE for an aircraft is considered to be a rather long-duration error, which will be different for each aircraft type and may be different for each airframe within an aircraft type, the TVE sample should reflect a census of the ASE of altimetry systems used, or likely to be used, in RVSM (between FL 290 and FL 410 inclusive) airspace because undetected large ASE adversely influences risk. Such a census may be a practical impossibility. Thus, it will be important during risk assessment to consider what the ASEs of airframes that are not included in the TVE sample may be in view of the ASE of identical aircraft types observed in the sample. The AAD component has been observed to reflect ATC operational conditions, such as areas where flights transition between flight levels, and meteorological environments as well as variations due to aircraft types and airspace users. Thus, the TVE sample should reflect these conditions and environments to the extent possible but, ideally, in the proportions in which they occur in RVSM airspace. As with the considerations that apply to observations of the ASE component of TVE, risk assessment should take into account the proportions in which all conditions relevant to adequate representation of AAD are present in any TVE sample.

Estimation of the probability of vertical overlap, Pz(1 000)

4.24 There were two methods adopted in the RGCSP analysis to model the observed height-keeping errors. In the first method, an analytical probability density function (PDF) is fitted directly to the TVE data and is then self-convoluted to assess the vertical overlap probability. For the second method, individual PDFs are fitted to the ASE results, broken down per aircraft group, and then re-combined in the proportions that these aircraft groups cross the RVSM airspace under consideration. The aggregate ASE distribution is then numerically convoluted with the PDF for the AAD data to produce a TVE distribution, termed TVE_{syn}. A self-convolution of this TVE_{syn} distribution is performed to obtain the vertical overlap probability.

4.25 The second method is more complicated to perform but is likely to be more accurate since it takes account of how well the monitoring sample matches the overall situation in the airspace under consideration. For small monitoring samples, this is particularly important, although it is then difficult to obtain enough data to fit distributions to the ASE data for individual aircraft groups. For large monitoring samples, it may be that the monitoring sample is sufficiently close (in terms of aircraft type proportions) to the overall situation in the airspace, thus making it possible to fit a PDF directly to the TVE data.

5. ASSESSMENT AND EVALUATION OF OPERATIONAL ERRORS AND IN-FLIGHT CONTINGENCIES

5.1 As set out in 1.1.10 and 5.3.1 to 5.3.3 of the main text of this manual, the level of collision risk resulting from errors in ATC instructions and emergency procedures in RVSM airspace needs to be assessed in addition to that resulting from technical height-keeping deviations. The types of errors and their possible consequences may vary from region to region.

5.2 To assist in the assessment of large height deviations (LHDs), a regional or State-based Scrutiny Group should be established to support the RMA monitoring function. A Scrutiny Group is comprised of operational and technical subject matter experts that support the evaluation and classification of LHDs. A Scrutiny Group is an important component of safety management as it enables the focussing of operational expertise to analyse the circumstances relevant to operational errors and to link the types of events in an airspace to trends in safety-related performance. During any analysis of the data and performance trends from an operational perspective, the Scrutiny Group should consider the effect of standing procedures and practices and review these in relation to accepted best practice.

5.3 The activities undertaken by a Scrutiny Group directly support the principles of safety management by “completing the safety cycle.” This is accomplished by synthesizing raw data in relation to current practices into recommendations for change of policies, practices and procedures which improve the safety of the airspace. Recommendations made by a regionally established Scrutiny Group typically proceed through the hierarchy of regional groups to the relevant PIRG for action by States. Where a State-based Scrutiny Group is established, recommendations from that group will normally be coordinated directly with participants in the airspace usage, such as operators and relevant authorities.

5.4 The responsible RMA(s) should coordinate with the PIRG to establish a Regional Scrutiny Group, or with relevant State organizations to establish a State-based Scrutiny Group. Further guidance on the establishment of a Scrutiny Group is contained in the *Manual of Operating Procedures and Practices for Regional Monitoring Agencies in relation to the use of a 300 m (1 000 ft) Vertical Separation Minimum Between FL 290 and FL 410 inclusive* (Doc 9937).

5.5 As guidance, the following briefly summarizes two approaches to the assessment of operational errors and in-flight contingencies that have been developed in the context of the NAT and the EUR Regions.

NAT Region

5.6 The NAT approach comprises the following elements:

- a) definition of types of errors on the basis of their cause;
- b) classification of errors for risk assessment purposes;
- c) determination of appropriate parameter values for each error;

- d) estimation of probability of vertical overlap; and
- e) estimation of vertical collision risk.

5.7 The assessment begins by identifying what types of operational errors could exist in the airspace under consideration. In the NAT, large height deviations collected by the central monitoring agency (CMA) are divided into the following four main types:

- a) ATC-pilot loop errors and incorrect clearances;
- b) aircraft contingency events;
- c) deviations due to meteorological effects; and
- d) deviations due to an airborne collision avoidance system (ACAS).

Within each type, one or more error classes, characterized by different CMA codes, are defined as shown below. (There is an additional error class O, Other.) See the Supplement to NAT Doc 002 for a more detailed description of the various error classes.

ATC-pilot loop errors and incorrect clearances

- D: Failure to climb/descend as cleared;
- E: Climb/descent without ATC clearance;
- F: Entry to RVSM airspace at an incorrect level; and
- G: ATC FL re-clearance resulting in loss of lateral or longitudinal separation.

Aircraft contingency events

- A: Contingency action due to engine fault;
- B: Contingency action due to pressurization failure; and
- C: Contingency action due to other cause.

Deviations due to meteorological effects

- I(W): Aircraft unable to maintain level due to weather conditions.

Deviations due to ACAS

- H: Deviation resulting from ACAS resolution advisories.

5.8 The next step is to classify each LHD for risk assessment purposes as either risk bearing or non-risk bearing. In the NAT, an LHD is classified as non-risk bearing when it occurs wholly outside MNPS airspace or when it is explicitly stated that correct contingency procedures were followed and the aircraft turned off track prior to any change of level.

5.9 Risk-bearing height deviations are further broken down into those involving whole numbers of flight levels and those not involving whole numbers of flight levels.

5.10 During the development of an LHD involving whole numbers of flight levels, one or more intermediate flight levels may have been crossed. This is taken into account in the NAT approach through the following parameters of the incident:

- a) the time spent around levels crossed, if any;
 - 1) the number of flight levels crossed, if any;
 - 2) the rate of climb/descent; and
- b) the time spent in level flight at uncleared flight levels, if any.

Item b) is mainly related to ATC-pilot loop errors and incorrect clearances (error classes D, E, F, G); item a) is mainly related to aircraft contingency events (error classes A, B, C) but may also play a part in ATC-pilot loop errors and incorrect clearances.

5.11 It has been observed that the rate of climb/descent and the time spent in level flight at uncleared levels are rarely included in the incident reports. For those cases, cautious estimates have been developed for the NAT based on information from operators and other sources.

5.12 LHDs of a few hundred feet, but not involving whole numbers of flight levels, may occur as a result of turbulence or nuisance-ACAS resolution advisories. The parameters of this type of incident are the maximum deviation and the total duration from the start of the deviation until the cleared flight level is re-established. Again, cautious estimates of the latter have been developed for the NAT because information about the duration has been found to rarely be documented in the incident report.

5.13 Estimates of the probability of vertical overlap associated with the different types of risk-bearing large height deviations can be made using the individual parameters. The probability of vertical overlap for aircraft in level flight at uncleared levels is computed as the product of the proportion of total flying time spent at incorrect levels and the probability that two aircraft nominally flying at the same level are in vertical overlap. For aircraft slowly crossing an uncleared flight level, the probability of vertical overlap can be estimated as the ratio of the average height of an aircraft and the vertical separation minimum. (A more complicated relation is required for crossing an uncleared flight level at higher speeds.)

5.14 The probability of vertical overlap for large height deviations not involving whole numbers of flight levels is not estimated separately. Rather, the relative frequency for each deviation magnitude is estimated (by dividing its duration by the total MNPS system flight hours) and added to the distribution of AAD (cf. 4.6 and 4.18 of this Appendix). In this way, this type of LHD is included in the distribution of technical height-keeping errors and in the estimate of the technical risk.

5.15 The vertical collision risk associated with each LHD involving either flying at an uncleared level or crossing an uncleared level is calculated with the Reich CRM, where the probability of vertical overlap and the relative vertical velocity are dependent on the specific error. The individual vertical risk estimates are then combined into an overall estimate of the total vertical collision risk due to such LHDs.

EUR Region

5.16 In addition to the NAT approach, an approach based on hazard analysis has been developed for the EUR Region. A hazard identification process has resulted in two broad categories of hazards:

- a) loss of vertical separation following altitude deviations — the main type of scenario being failure to level at the assigned altitude (level “bust”) and the main causes being pilot error and pilot-ATC miscommunication; and

- b) loss of vertical separation due to ATC misjudgements — the main scenario being ATC placing two aircraft in close proximity during a climb or descent and the main causes appearing to be controller aberrations, problems in coordination between military and civil controllers, and coordination difficulties between controllers in different sectors.

5.17 An altitude deviation generally leads to one or more of the following:

- a) crossing one or more uncleared flight levels;
- b) joining an uncleared flight level; and
- c) levelling off between flight levels.

The approach then consists of determining the frequency of altitude deviations and calculating the associated probability of vertical overlap. The latter depends on the specific effects and the probability of ATC failing to intervene successfully.

5.18 An ATC misjudgement has been defined as a loss of vertical separation where both aircraft follow the instructed flight profiles. A key difference from altitude deviations is that misjudgements always occur in the context of another aircraft being in the near vicinity. The process developed involves first of all deriving the frequency of ATC misjudgements leading to the loss of vertical separation and dividing this frequency into components involving joining and crossing levels and involving different traffic directions. This is followed by determining ATC intervention probabilities for each component and combining collision risks in the absence of ATC with probabilities of failed ATC intervention.
